What are Mangroves?

Mangroves are shrubs and trees that dominate the coastal and estuarine shorelines in subtropical and tropical areas worldwide. They are usually associated with low energy coastlines. In Region IV mangroves are comprised of 3 species: red, black, and white mangroves.

Red mangroves usually occur seaward of the other two species, and are most severely affected by oil spills. Red mangroves can be easily identified by their curving prop roots. Black mangroves occur in the high inter-tidal area, and can be identified by their pneumatophores, or thin, finger-like exposed roots which are 3-6 inches tall. The prop roots and pneumatophores allow the red and black mangroves to exchange gases in sediment that is water saturated. White mangroves inhabit higher elevations, and are rarely impacted by marine oil spills.

are attached to the underwater portion of the prop roots are especially vulnerable. These oils generally evaporate rapidly and thus impacts occur mostly when large spills rapidly strand onshore. No. 2 fuel oil tends to be more persistent, particularly if it penetrates the substrate through animal burrows or trampling by responders.

also be used to collect sheens coming from oil that has already stranded. Snare booms are more effective in collecting heavier oils. Sorbents must be changed periodically as they become saturated with oil. Sorbents may also be used to wipe heavy accumulations of oil from prop roots in areas of firm substrate.

Red

Light fuels are also absorbed by the tree roots and can cause mortality in 24-48 hours in red mangroves and black mangroves.

Crude oils and heavy refined products such as Bunker C can coat the prop roots and pneumatophores, reducing the ability of the tree to exchange gases. These heavy oils will have long -term persistence, especially with heavy accumulations. This long term persistence may cause leaf loss and possibly death to heavily oiled trees. Recruitment of seedlings into the oiled area may also be affected.

Black

Light fuels are also absorbed by the tree roots and can cause mortality in 24-48 hours in red mangroves and black mangroves.

Crude oils and heavy refined products such as Bunker C can coat the prop roots and pneumatophores, reducing the ability of the tree to exchange gases. These heavy oils will have long -term persistence, especially with heavy accumulations. This long term persistence may cause leaf loss and possibly death to heavily oiled trees. Recruitment of seedlings into the oiled area may also be affected.

The Importance of Mangroves:

Mangroves are very important to the ecology and the economy of the regions where they occur. Mangroves provide a buffer to inland areas from devastating hurricane winds and deadly storm surges. Mangroves also trap and stabilize sediment. Many birds use mangrove areas as roosting and nesting locations. Finally, many important commercial and recreation species depend on mangroves for some aspect of their life cycle, as a nursery, shelter, and foraging.

Clean Up Options for Mangrove Environments:

Mangroves are the most sensitive shore-line habitat to oil spill effects. They are slow growing, sensitive to oil, and difficult to clean. They usually grow in low energy environments where oil can persist for years. These areas should receive the highest protection priority during a spill. Every effort should be made to minimize the amount of oil that is allowed to enter a mangrove area, without causing greater harm.

How Oil Effects Mangrove Environments:

Oil impacts to the mangrove community can vary depending on the type of oil, the amount of oil, and the duration of weathering.

Light, refined oils such as gasoline, jet fuel, and No. 2 fuel oil contain relatively high amounts of the most water soluble and toxic compounds in oils. The rich assemblages of plants and animals that

Flushes:

Heavy accumulations of liquid oil can be flushed with low pressure (<10psi) flooding. Flushing should be only used on an ebbing tide, with the appropriate collection devices in place. Often there is no access, limiting the use of flushing. This technique should not be used if there is sediment disturbance or mixing of oil into the substrate.

Oiled Debris Removal:

Heavy accumulations of liquid oil can be flushed with low pressure (<10psi) flooding. Flushing should be only used on an ebbing tide, with the appropriate collection devices in place. Often there is no access, limiting the use of flushing. This technique should not be used if there is sediment disturbance or mixing of oil into the substrate.

Natural Recovery:

Mangrove environments often have a wrack line along the high tide and storm lines. If this wrack becomes oiled it can be a source of chronic sheening and should be removed. Care must be taken not to disturb the substrate. Vegetation should never be cut or removed.

When cleanup activity causes more environmental damage than the oil, natural recovery should be considered. It is the preferred method for lighter fuels such as gasoline and jet fuel. Natural recovery should also be considered when heavy products are located deep in the mangrove forest or when removal causes mixing with sediments. The placement of sorbents is often used to recover sheens released during natural removal. Any cleanup activity that disturbs nesting birds should be postponed until the young have fledged.
